## Introduction

The Atchafalaya Basin Program's East Grand Lake project (EGL) is the state of Louisiana's restoration plan for a 202,424 acre portion of the Atchafalaya Basin bound by Bayou Sorrel, the Atchafalaya River, and the East Atchafalaya Guide Levee (LDNR 2012). The project area was partitioned into three regions: Upper Region, Lower Region and Western Region. These regions were then subdivided into smaller Assessment Units (AU) to aid in the planning and implementation of project features. The Nature Conservancy's (TNC) Atchafalaya Basin Preserve falls within the Upper Region and spans a portion of AUs 1, 2, 3, 5, and 6 (Figure 1).

The main strategy of the EGL Project is to improve the north to south flow of water through the area during moderate river stages (i.e., 3.0-3.6 m at Butte La Rose) to improve water quality and ecosystem health. The swamps in this area suffer from poor water quality due to historic hydrologic alterations. Currently, Atchafalaya River water tends to stay confined within the banks of distributary channels and does not flood the backswamps until extremely high-water levels occur with high river flow. For example, water entering Bayou Sorrel heads south through School Board Canal, Indigo Bayou, Salt Mine Bayou, and the GIWW, but tends to pass through those channels with little to no communication with adjacent swamps until water levels are high (LDNR 2012). Significant overbank flow into those AUs from Bayou Sorrel does not happen until the Butte La Rose gauge is greater than 5.5 m. Below this stage, inflow is limited to point source locations including input from the Florida Gas pipeline. The EGL project consists of hundreds of separate project features, but within the Upper Region there are two major types of features: those that increase the flow of river water from channels into the backswamps at the north end of AU's and those that increase drainage of water at the southern end of AU's. To date, there has been no work done on an AU that incorporates both types of features.

The goal of this monitoring program is to evaluate the effectiveness of hydrologic restoration done as part of the EGL Project. This project has many restoration features, and it will be necessary to assess the effectiveness of selected individual project features, as well as the combined effects of multiple project features. By providing a network of stations across the area, we can assess not only the areas affected by project features, but also the ecological condition of areas not being restored (i.e., reference sites). Therefore, a small network of stations, similar to that employed by the Coastwide Reference Monitoring System (CRMS) has been deployed throughout the study area (CRMS 2014). This report is a summary of the pre-restoration monitoring activities conducted in during the 2019 calendar year on TNC and adjacent State lands to support East Grand Lake restoration activities.

## Methods

### *Site description*

The Nature Conservancy's Atchafalaya Basin Preserve was established in 2015 in the vicinity of Bayou Sorrel. The Preserve consists of five distinct tracts that are surrounded by a mix of private

and State Lands (Figure 1). The habitat is predominantly baldcypress/water tupelo swamp, with bottomland hardwoods dominating the higher ground along channels and canals.

#### *Data collection*

Seven monitoring stations were setup in the Atchafalaya Basin Preserve and adjacent State Lands in 2016 (Figure 1). Each station consists of a fixed wooden structure with a 4" perforated PVC pipe that houses a YSI Exo2 multiparameter sonde. Each sonde was equipped with sensors to measure water level, dissolved oxygen, turbidity, specific conductance, and temperature. The sondes are also equipped with a central wiper which cleaned the sensors twice an hour to prevent biofouling. The sondes collected data every hour, and data were then binned to give daily averages for analysis. Sondes were deployed throughout the year except for periods of regular maintenance and calibration. Additionally, low water levels during periods of the year prevented sonde deployment and data collection. Water monitoring equipment was deployed for two separate periods during the year. The first deployment began on 18 January 2019 during an already ongoing high-water event in the Atchafalaya Basin. The sondes were then retrieved on 5 August 2019 for data download and calibration. During the first deployment, high water prevented sonde service at the regular intervals, and as a result, the batteries on the sonde at station AU6 expired on 15 May. All other stations collected data for the entire period. The second deployment began on 6 November and is currently ongoing.

Surface water sampling trips occurred on 21 March, 29 April, 11 July, 5 August, and 6 November 2019. Duplicate samples were taken from 45 cm to 60 cm below the water's surface and analyzed for total suspended solids, total nitrogen, NH<sub>4</sub>-N, NO<sub>3</sub>-N, and PO<sub>4</sub>-P. Total suspended solids of the samples were determined by filtering a well-mixed volume of the water through a pre-weighed glass fiber filter. The filters were then dried at 60° C for 24-hours and reweighed. Total suspended solid (TSS) concentrations were calculated as the increase of weight on the filter divided by the volume of water filtered. Nutrient concentrations were determined by analyses at the Wetland Biogeochemistry Analytical Laboratory at Louisiana State University following standard EPA methods. In addition to the collection of water samples, a YSI ProDSS multiparameter water quality meter was deployed to record triplicate water temperatures, dissolved oxygen, specific conductance, and turbidity at each of the sampling locations. The sampling trips in March, April and July focused on water quality in the distributary channels around Bayou Sorrel (Figure 2), while the trips in August and November added water samples from the backswamp monitoring stations (Figure 1).

Surface accretion is being monitored using the feldspar horizon technique (Cahoon and Turner 1989). A one cm thick layer of feldspar clay was laid down over a quarter-meter squared area at six different locations consisting of three plots in two-separate Assessment Units in December 2016 (Figure 3). Additional feldspar clay was laid down at each of the backswamp monitoring

stations on 15 August 2018. Surface accretion was not measured in 2019 due to the extended period of high-water restricting access to the soil surface.

Long-term forest monitoring plots were setup in the project area in 2019. Triplicate 20m x 20m plots were setup along transects with three different elevation zones. Transects were placed in areas expected to be impacted by EGL restoration activities and areas outside the influence of individual project elements. The goal of the forest monitoring is to assess changes in forest structure, and individual tree growth rates, as a result of the EGL restoration activities.

To date, no restoration has been conducted in the area, so all data presented within this report can be considered pre-restoration monitoring.

## Results

### *Basinwide conditions*

Water levels in the Atchafalaya Basin were already high when 2019 began and stayed elevated until August. The Atchafalaya River at Butte La Rose stayed above bankfull stage from the end of February until the beginning of August (Figure 4). The extended period of high water meant water was flowing overbank out of Bayou Sorrel for nearly half the year and influencing water quality in the backswamp. In August water levels fell precipitously, and water levels in September were within the long-term average (Figure 5). The period of normal water levels was short-lived and water levels were again rising in the Basin in October.

### *Backswamp water quality – continuous measurements*

The magnitude and duration of high-water in 2019 had a significant, and positive impact, on water quality in the backswamp. Water levels peaked on the Atchafalaya River at Butte La Rose (BLR) on 15 March at 6.31 m (20.7 ft) and crested at the seven backswamp monitoring stations the next day (Figure 6). Similar to the previous three years, water levels in Bayou Sorrel and along the GIWW were high enough to overtop banks and connect the backswamp to a source of river water. However, determining when that connection was initiated between the channels and the backswamp was difficult as the sites may have already been connected when sondes were deployed in mid-January. Cold river water (Figure 7) moving through the backswamp kept dissolved oxygen concentrations above 2 mg/l for nearly the entire 8-month deployment at all sites except T3 (Figure 8). Dissolved oxygen at site T3 stayed near anoxic except for the periods of maximum river stage when river water came overbank from Bayou Sorrel and penetrated further into the swamp to the north. In early August, water levels were dropping, water temperatures were rising, and the backswamp monitoring stations began to experience hypoxic conditions prior to sonde retrieval.

Specific conductance was similar between all backswamp monitoring stations, except site T3 (Figure 9; Table 1) and largely corresponded to specific conductance of the Atchafalaya River (Figure 10). Specific conductance at site T3 was similar to the other stations for most of the deployment, however, there was a large spike in specific conductance from mid-April to mid-May

that corresponded to a drop in water levels, a drop in turbidity, and a drop in dissolved oxygen at the site. As water began to fall after the second flood peak in late-May, specific conductance at the backswamp monitoring stations began to rise.

Turbidity was variable at the backswamp monitoring stations, with AU2S having the highest recorded turbidity during a spike in early March (Figure 11). Turbidities stayed below 50 FNU during most of the deployment, except for sites AU2S and AU2N both having periods of time above 50 FNU. On average, AU5 had the lowest turbidity, and AU2S had the highest turbidity (Table 1).

#### *Distributary water quality – discrete measurements*

The surface water sampling events in March, April, and July were all completed during high river stages – over 17.5ft on the Butte La Rose gage. This led to well mixed conditions with turbid Atchafalaya River water flowing overbank along Bayou Sorrel and many of the local distributaries. Despite those conditions, there were observable differences in the surface waters surrounding Bayou Sorrel (Table 2). For example, turbidity, TSS, and dissolved oxygen tended to be highest in the stations near the Atchafalaya River and decreased with distance from the river, while specific conductance and water temperatures remained very similar among all stations. Turbidity proved to be a good predictor of TSS in the surface water, however the exact relationship varied by sampling event (Figure 12). For the individual sampling events the turbidity values explained 89 to 98% of the variation in the TSS data, while taken cumulatively the turbidity values explained 72% of the data ( $TSS = 1.9854 * Turbidity - 15.578$ ). There was no discernable pattern to the nutrient concentrations in the surface waters around Bayou Sorrel (Table 2).

#### *Backswamp water quality – discrete measurements*

The backswamp water sampling in August occurred during a period of falling water levels in the Basin, but the stage (16.7ft at Butte La Rose) was still high enough to maintain a connection between the distributaries and the backswamp in many locations. This was evidenced by similar specific conductance levels between the backswamp and distributary network samples (Table 3) and direct observation on the ground. Despite this connection, there was lower turbidity, TSS, and dissolved oxygen concentrations in the backswamp compared to the surrounding channels (Table 3). Dissolved oxygen was higher at stations AU1 and AU3 because the samples were taken higher in the water column than at all the other stations to avoid disturbing the sediment surface. Nutrient concentrations were similar at most sampling stations, except for T3 and AU5 which had lower nitrate concentrations and higher phosphate concentrations (Table 3).

## **Discussion**

Water levels in the Atchafalaya Basin were high enough to cause overbank flooding along Bayou Sorrel and the GIWW for the fourth year in a row. We were able to document the impact overbank flooding had on water quality (i.e., dissolved oxygen) through our series of monitoring

stations for the third consecutive flood event. This year, as in 2017 and 2018, we saw that when the backswamp was connected to a source of river water, dissolved oxygen concentrations in the backswamp increased. These results indicate that a restoration action that increases the amount of time there is a connection between river water and the backswamp has the potential to increase dissolved oxygen concentrations in the backswamp and improve aquatic habitat quality.

Water quality measurements in surface waters during the discrete water sampling events showed water in the distributary network is not homogenous, and turbidity and TSS can vary from one location to the next. The sampling stations near the proposed input features of the East Grand Lake restoration, BS1 and BS2 along Bayou Sorrel and Launch near the Bayou Sorrel public boat launch (Figure 2), regularly had some of the lowest TSS and turbidity concentrations during the discrete samplings. The TSS concentrations at these stations are lower than what has been reported in the Basin previously, although previously published measurements of turbidity or TSS tend to be focused on the mainstem of the Atchafalaya River and/or incorporate depth-integrated samples (USCOE 2011; Kroes and Kramer 2013; Rosen and Xu 2015). The previous studies are good for developing sediment budgets for the Basin as a whole, but not as relevant to understanding sediment dynamics of the planned East Grand Lake restoration that only involves shallow inputs of water from the top few feet of the water column. The TSS concentrations reported here are lower than other estimates, but the potential sediment load is also dependent on the length of time the water is flowing through the swamp. The flood in 2019 was long in duration, so there was the potential for high amounts of sediment to be flowing through the swamp. Sediment laden water flowing through a swamp does not indicate there will be sedimentation, thus future measurements of surface accretion in the backswamp will be useful in understanding the magnitude of sedimentation on the swamp floor from this extended flood. Additionally, the central and southeastern portions of the Atchafalaya Basin are known to have subsidence rates in excess of 20 mm/yr, so sedimentation on the soil surface does not necessarily equal an increase in elevation but may just be offsetting subsidence and sea level rise (Kroes et al. 2019).

The impact Hurricane Barry had on water quality appeared to be minor. Water levels in the backswamp increased as the storm passed on 13 July, likely as a result of the wind and storm surge temporarily reducing the discharge of the Atchafalaya River at Morgan City by nearly two orders of magnitude (Figure 13) and backing water up in the Basin. There was also a slight dip in water temperatures and specific conductance indicating locally heavy rainfall. Interestingly, the impacts to turbidity and dissolved oxygen were not as easily discernable. Following storm passage there may have been slight decreases in dissolved oxygen and turbidity at sites AU1, AU2N, AU3, and AU5 but the effect was minor. In addition, water levels began dropping basinwide after storm passage, and the backswamp became disconnected which led to lower turbidities, specific conductance, and dissolved oxygen concentrations in the weeks following the storm.

Monitoring in 2019 again showed that when the backswamp is connected to a source of flowing river water dissolved oxygen concentrations increase. This improves aquatic habitat for fish and crawfish (Bonvillain et al. 2013; Bonvillain et al. 2015; Kong et al. 2019) and may improve tree growth (McAlhaney 2018). Furthermore, TSS in the surface water near the proposed East Grand Lake restoration is lower than other reported values for the Atchafalaya Basin, which reduces the potential for infilling of the backswamp following restoration. Sedimentation that does occur may only be offsetting sea-level rise and regional subsidence (Kroes et al. 2019).

## Future Monitoring Activities

Monitoring activities planned for 2020 include continuation of the continuous backswamp water quality sampling, discrete backswamp and channel water quality, forest structure surveys, and surface accretion measurements. All monitoring activities planned for 2020 will add to the knowledge base of ecosystem function in the Upper Region of the East Grand Lake project area prior to hydrologic restoration.

**Appendix 2.** Photographs of monitoring activities.

Fig A1. During sonde deployment at site AU6 on 6 November 2019, Will DeGravelles points towards the high-water mark left on the tree during the flood earlier in the year.

Fig A2. Swamp privet (*Forestiera acuminata*) often forms a dense tangle of branches making access to the backswamp monitoring stations difficult.

Fig A3. Backswamp monitoring station AU2S on 12 December 2019.

Fig A4. Banding and tagging trees to measure growth rates on 12 December 2019.

Fig A5. Overbank flooding along the Florida Gas Canal on 5 August 2019.

Fig A6. Fire ants cling to anything they can find during high water in 2019.

Fig A7. Water coming over bank near the old Cannon Bayou channel on 18 January 2019.

Fig A8. Turbid river water in the Florida Gas Canal meets blackwater in the backswamp on a rainy 3 January 2019.

Fig A9. Turbid water from the Florida Gas Canal snakes its way into the backswamp through an old distributary channel near the AU1 monitoring station on 3 January 2019.

Fig A10, Before and after comparison of the YSI Exo2 water quality sondes deployed at the seven backswamp monitoring stations.
